Modern high frequency, high performance system-on-chip design is heading to include more and more analog or mixed signal circuits as well as digital blocks. As the complexity of a system grows, it becomes more important to implement the system simulation and top-down design methodology. In this paper, we have designed a delay locked loop using Verilog and Xilinx. Considering the rapid growth in computer automation and computer networking sector, FPGA implementation technique of DLL has been adopted in this paper. DLL model basically used for synchronization of closed loop RF control signals. In ASIC system sometimes it is very important to synchronize the input signal with the output signal. Synchronous DLL can be used for this purpose. This paper has considered the minimum number of devices like Flip Flop, comparator, adder or subtractor due to enhance the efficiency of the system and the time delay of DLL is also considered to be much less and also design vertex FPGA series to provide zero propagation delay, low clock skew between output clock signals distributed throughout the device, and advanced clock domain control.

**Keywords:** Delay locked loop, voltage controlled delay, Variable delay line

**INTRODUCTION**

As FPGAs grow in size, quality on-chip clock distribution becomes increasingly important. Clock skew and clock delay impact device performance and the task of managing clock skew and clock delay with conventional clock trees becomes more difficult in large devices. The Virtex series of devices resolve this potential problem by providing fully digital dedicated on-chip DLL circuits that provide zero propagation delay and low clock skew between output clock signals distributed throughout the device.

Each DLL can drive up to two global clock routing networks within the device. The global clock distribution network minimizes clock skews due to loading differences. By monitoring a sample of the DLL output clock, the DLL can compensate for the delay on the routing network, effectively eliminating the delay from the external input port to the individual clock loads with in the device.

---

1. MIET Engineering College, Trichy - 620007.

In addition to providing zero delay with respect to a user source clock, the DLL can provide multiple phases of the source clock. The DLL can also act as a clock doubler or can divide the user source clock by up to 16. Clock multiplication gives the designer a number of design alternatives. For instance, a 50 MHz source clock doubled by the DLL can drive an FPGA design operating at 100 MHz. This technique can simplify board design because the clock path on the board no longer distributes such a high-speed signal. A multiplied clock also provides designers the option of time-domain multiplexing, using one circuit twice per clock cycle, consuming less area than two copies of the same circuit. Two DLLs can be connected in series to increase the effective clock multiplication factor to four. The DLL can also act as a clock mirror. By driving the DLL output off-chip and then back in again, the DLL can be used to deskew a boardlevel clock between multiple devices. The DLL can delay the completion of configuration until after DLL locks to guarantee the system clock is established prior to initiating the device. By taking advantage of the DLL to remove on-chip clock delay, the designer can greatly simplify and improve system-level design involving high fanout, high-performance clocks.

**RELATED WORK**

**Delay-Locked Loop**

As shown in Figure 1, a DLL in its simplest form consists of a variable delay line and control logic. The delay line produces a delayed version of the input clock CLKIN. The clock distribution network routes the clock to all internal registers and to the clock feedback CLKFB pin. The control logic must sample the input clock as well as the feedback clock in order to adjust the delay line.

![Figure 1: Delay Locked Loop](image)

Delay lines can be built using a voltage controlled delayor as a series of discrete delay elements. For optimum performance, the Virtex DLL uses a discrete digital delayline. A DLL works by inserting delay between the input clock and the feedback clock until the two rising edges align, putting the two clocks 360° out of phase (meaning they are in phase). After the edges from the input clock line up with the edges from the feedback clock, the DLL “locks.” As long as the circuit is not evaluated until after the DLL locks, the two clocks have no discernible difference. Thus, the DLL output clock compensates for the delay in the clock distribution network, effectively removing the delay between the source clock and its loads.

The circuit diagram of a conventional deskew buffer with duty cycle correction is illustrated in Figure 2. Its main architecture is based on DLL with a DCC circuitry in front of the output buffer (OB). Hence the output clock can satisfy the requirement of 50% duty cycle. The controller accepts the lead-lag information derived from the phase detector (PD) so as to adjust the output delay of the delay line. The DCC can be of either analog or digital type.
B. Implementation

Implementation of the DLL or PLL can be accomplished using either analog or digital circuitry; each holds its own advantages. An analog implementation with careful design can produce a DLL or PLL with a finer timing resolution. Analog implementations can additionally take less silicon area. Conversely, digital implementations offer advantages in noise sensitivity, lower power consumption, and jitter performance. Digital implementations also provide the ability to stop the clock, facilitating power management. Analog implementations can require additional power supplies, require close control of the power supply, and pose problems in migration to new process technologies.

C. DLL vs. PLL

When it comes to choosing between a PLL or a DLL for a particular application, the differences in the architectures must be understood. The oscillator used in the PLL inherently introduces in stability and an accumulation of phase error. This in turn degrades the performance of the PLL when attempting to compensate for the delay of the clock distribution network.

Conversely, the unconditionally stable DLL architecture does not accumulate phase error. For this reason, for delay compensation and clock conditioning, DLL architecture should be used. On the other hand, the PLL typically has an advantage when it comes to frequency synthesis.

EXPERIMENTAL EVALUATION

Figure 3 shows the DLL primitives. These symbols provide access to the complete set of DLL features when implementing more complex applications.

BUFGDLL Pin Descriptions

The BUFGDLL macro is used as the simplest way to provide zero propagation delay for a high fanout on-chip clock from an external input. This macro uses the IBUFG, CLKDLL, and BUFG primitives to implement the most basic DLL application, as shown in Figure 5.

Clock Output — O

The clock output pin O represents a delay-compensated version of the source clock (I) signal. This signal, sourced by a global clock buffer BUFG symbol, takes advantage of the dedicated global clock routing resources of the device. The library CLKDLL primitives provide access to the complete set of DLL features needed when implementing more complex applications with the DLL.

Source Clock Input — CLKIN

The CLKIN pin provides the user source clock (the clock signal on which the DLL operates) to the DLL. The CLKIN frequency must fall in the ranges specified in the data sheet. The clock input signal can be provided by one of the following:

- BUFG — Internal global clock buffer
- IBUFG — Global clock input buffer on the same edge of the device (top or bottom)
- IO_LVDS_DLL — the pin adjacent to a global clock pin.

Feedback Clock Input — CLKFB

The DLL requires a reference or feedback signal to provide the delay-compensated output. Only the CLK0 or CLK2X DLL outputs should be connected to the feedback clock input (CLKFB) pin to provide the necessary feedback to the DLL. The feedback clock input signal can be driven by an internal global clock buffer (BUFG), one of the global clock input buffers (IBUFG) on the same edge of the device (top or bottom). If an IBUFG sources the CLKFB pin, the following special rules apply:

1. An external input port must source the signal that drives the IBUFG input pin.
2. The CLK2X output must feedback to the device if both the CLK0 and CLK2X outputs are driving off-chip devices.

3. That signal must directly drive only OBUFs and nothing else.

4. These rules enable the software determine which DLL clock output sources the CLKFB pin.

**Reset Input — RST**

When the reset pin RST activates, the LOCKED signal deactivates within four source clock cycles. The RST pin, active High, must either connect to a dynamic signal or tied to ground. As the DLL delay taps reset to zero, glitches can occur on the DLL clock output pins.

Activation of the RST pin can also severely affect the duty cycle of the clock output pins. Furthermore, the DLL output clocks no longer deskew with respect to one another. The DLL must be reset:

1. When the input clock frequency changes.
2. If the device is reconfigured in Boundary-Scan mode.
3. If the device undergoes a hot swap.
4. After the device is configured if the input clock is not stable during the startup sequence.

In each case, the DLL RST pin can be driven by internal logic or routed to a user I/O and driven externally.

**2x Clock Output — CLK2X**

The output pin CLK2X provides a frequency-doubled clock with an automatic 50/50 duty-cycle correction.

Until the CLKDLL has achieved lock, the CLK2X output appears as a 1x version of the input clock with a 25/75 duty cycle. This behavior allows the DLL to lock on the correct edge with respect to source clock. This pin is not available on the CLKDLLHF primitive.

**Clock Divide Output — CLKDV**

The clock divide output pin CLKDV provides a lower frequency version of the source clock.

The CLKDV_DIVIDE property controls CLKDV such that the source clock is divided by N where N is either 1.5, 2, 2.5, 3, 4, 5, 8, or 16.

The CLKDV output pin is provided with automatic duty cycle correction. The CLKDV output pin has a 50/50 duty cycle only for all values of the division factor N except for non-integer division in High Frequency (HF) mode.

For division factor 1.5 the duty cycle in the HF mode is 33.3% High and 66.7% Low. For division factor 2.5, the duty cycle in the HF mode is 40.0% High and 60.0% Low.

**1x Clock Outputs — CLK[0|90|180|270]**

The DLL provides duty cycle correction on all 1x clock outputs such that all 1x clock outputs by default have a 50/50 duty cycle. The DUTY_CYCLE_CORRECTION property (TRUE by default), controls this feature. In order to deactivate the DLL duty cycle correction, attach the DUTY_CYCLE_CORRECTION=FALSE
property to the DLL symbol. When duty cycle correction deactivates, the output clock has the same duty cycle as the source clock.

The DLL clock outputs can drive an OBUF, a BUFG, or they can route directly to destination clock pins. The DLL clock outputs can only drive the BUFGs that reside on the same edge (top or bottom).

**Locked Output — LOCKED**

In order to achieve lock, the DLL might need to sample several thousand clock cycles. After the DLL achieves lock, the LOCKED signal activates. The DLL timing parameter section of the data sheet provides estimates for locking times. To guarantee that the system clock is established prior to the device “waking up,” the DLL can delay the completion of the device configuration process until after the DLL locks. The STARTUP_WAIT property activates this feature.

Until the LOCKED signal activates, the DLL output clocks are not valid and can exhibit glitches, spikes, or other spurious movement. In particular, the CLK2X output appears as a 1x clock with a 25/75 duty cycle.

**Further Implementation**

Figure 5 is composed of five major configurable elements. IOBs provide the interface between the package pins and the internal logic. CLBs provide the functional elements for constructing most logic. Dedicated block RAM memories of 4096 bits each, Clock DLLs for clock distribution delay compensation and clock domain control, Versatile multi-level interconnect structure. As can be seen in Figure 3, the CLBs form the central logic structure with easy access to all support and routing structures. The IOBs are located around all the logic and memory elements for easy and quick routing of signals on and off the chip. Values stored in static memory cells control all the configurable logic elements and interconnect resources.

These values load into the memory cells on power-up, and can reload if necessary to change the function of the device. Each of these elements will be discussed in detail in the following sections.

**Configurable Logic Block**

The basic building block of the Spartan-IIE FPGA CLB is the logic cell (LC). An LC includes a 4-input function generator, carry logic, and storage element. The output from the function generator in each LC drives the CLB output or the D input of the flip-flop. Each Spartan-IIE FPGA CLB contains four LCs, organized in two similar slices.

![Figure 5: FPGA architecture with DLL](image)

**DLL Output Characteristics**

The DLL provides duty cycle correction on all 1x clock outputs such that all 1x clock outputs by default have a 50/50 duty cycle. The DUTY_CYCLE_CORRECTION property (TRUE
by default), controls this feature. In order to deactivate the DLL duty cycle correction, attach the DUTY_CYCLE_CORRECTION=FALSE property to the DLL symbol. When duty cycle correction deactivates, the output clock has the same duty cycle as the source clock.

The DLL clock outputs can drive an OBUF, a BUFG, or they can route directly to destination clock pins. The DLL clock outputs can only drive the BUFGs that reside on the same edge (top or bottom).

**CONCLUSION**

DLL is widely used in wireless communication systems as well as telecommunication system. These dedicated DLLs can be used to implement several circuits, which improve and simplify system-level design. FPGA implementation ensures easy and computer control over the system. This paper has discussed the PLL basic structure and designed a PLL that can be used efficiently for device synchronization purpose. Xilinx is used for designing the schematic diagram using the RTL logic. And also designed FPGA with DLL. The Virtex™ FPGA series offers fully digital dedicated on-chip Delay-Locked Loop (DLL) circuits providing zero propagation delay, low clock skew between output clock signals distributed throughout the device, and advanced clock domain control.
